Amines and Amides*

OpenStax

By the end of this section, you will be able to:

• Describe the structure and properties of an amine
• Describe the structure and properties of an amide

Amines are molecules that contain carbon-nitrogen bonds. The nitrogen atom in an amine has a lone pair of electrons and three bonds to other atoms, either carbon or hydrogen. Various nomenclatures are used to derive names for amines, but all involve the class-identifying suffix -ine as illustrated here for a few simple examples:

\[
\begin{align*}
\text{methyl amine} & : & \text{CH}_3\text{N}-\text{H} \\
\text{dimethyl amine} & : & \text{CH}_3\text{N}-\text{CH}_3 \\
\text{trimethyl amine} & : & \text{CH}_3\text{N}-\text{CH}_3
\end{align*}
\]

In some amines, the nitrogen atom replaces a carbon atom in an aromatic hydrocarbon. Pyridine (Figure 1) is one such heterocyclic amine. A heterocyclic compound contains atoms of two or more different elements in its ring structure.

Figure 1: The illustration shows one of the resonance structures of pyridine.

NOTE: The genetic material for all living things is a polymer of four different molecules, which are themselves a combination of three subunits. The genetic information, the code for developing an organism, is contained in the specific sequence of the four molecules, similar to the way the letters of the alphabet can be sequenced to form words that convey information. The information in a DNA sequence is used to form two other types of polymers, one of which are proteins. The proteins interact to form a specific type of organism with individual characteristics.

A genetic molecule is called DNA, which stands for deoxyribonucleic acid. The four molecules that make up DNA are called nucleotides. Each nucleotide consists of a single- or double-ringed molecule containing nitrogen, carbon, oxygen, and hydrogen called a nitrogenous base. Each base is bonded to a five-carbon sugar called deoxyribose. The sugar is in turn bonded to a phosphate group ($\text{PO}_4^{3-}$) When new DNA is made, a polymerization reaction occurs that binds the phosphate group of one nucleotide to the sugar group of a second nucleotide. The nitrogenous bases of each nucleotide stick out from this sugar-phosphate backbone. DNA is actually formed from two such polymers coiled around each other and held together by hydrogen bonds between the nitrogenous bases. Thus, the two backbones are on the outside of the coiled pair of strands, and the bases are on the inside. The shape of the two strands wound around each other is called a double helix (see Figure 2).

It probably makes sense that the sequence of nucleotides in the DNA of a cat differs from those of a dog. But it is also true that the sequences of the DNA in the cells of two individual pugs differ. Likewise, the sequences of DNA in you and a sibling differ (unless your sibling is an identical twin), as do those between you and an unrelated individual. However, the DNA sequences of two related individuals are more similar than the sequences of two unrelated individuals, and these similarities in sequence can be observed in various ways. This is the principle behind DNA fingerprinting.
which is a method used to determine whether two DNA samples came from related (or the same) individuals or unrelated individuals.

**Figure 2:** DNA is an organic molecule and the genetic material for all living organisms. (a) DNA is a double helix consisting of two single DNA strands hydrogen bonded together at each nitrogenous base. (b) This detail shows the hydrogen bonding (dotted lines) between nitrogenous bases on each DNA strand and the way in which each nucleotide is joined to the next, forming a backbone of sugars and phosphate groups along each strand. (c) This detail shows the structure of one of the four nucleotides that makes up the DNA polymer. Each nucleotide consists of a nitrogenous base (a double-ring molecule, in this case), a five-carbon sugar (deoxyribose), and a phosphate group.

Using similarities in sequences, technicians can determine whether a man is the father of a child.
(the identity of the mother is rarely in doubt, except in the case of an adopted child and a potential birth mother). Likewise, forensic geneticists can determine whether a crime scene sample of human tissue, such as blood or skin cells, contains DNA that matches exactly the DNA of a suspect.

**Note:** Watch this video animation[^1] of how DNA is packaged for a visual lesson in its structure.

Like ammonia, amines are weak bases due to the lone pair of electrons on their nitrogen atoms:

\[
\begin{align*}
\text{H} - \text{N} - \text{H} + \text{H}^+ & \rightarrow \quad \left[ \begin{array}{c} 
\text{H} \\
\text{H} \\
\text{H} \\
\end{array} \right] + \\
\text{ammonia} & \rightarrow \quad \text{ammonium ion} \\
\text{CH}_3 - \text{N} - \text{H} + \text{H}^+ & \rightarrow \quad \left[ \begin{array}{c} 
\text{H} \\
\text{CH}_3 \\
\text{H} \\
\end{array} \right] + \\
\text{methyl amine} & \rightarrow \quad \text{methyl ammonium ion}
\end{align*}
\]

The basicity of an amine’s nitrogen atom plays an important role in much of the compound’s chemistry. Amine functional groups are found in a wide variety of compounds, including natural and synthetic dyes, polymers, vitamins, and medications such as penicillin and codeine. They are also found in many molecules essential to life, such as amino acids, hormones, neurotransmitters, and DNA.

**Note:** Since ancient times, plants have been used for medicinal purposes. One class of substances, called alkaloids, found in many of these plants has been isolated and found to contain cyclic molecules with an amine functional group. These amines are bases. They can react with \( \text{H}_3\text{O}^+ \) in a dilute acid to form an ammonium salt, and this property is used to extract them from the plant:

\[
\text{R}_3\text{N} + \text{H}_3\text{O}^+ + \text{Cl}^- \rightarrow [\text{R}_3\text{NH}^+] \text{Cl}^- + \text{H}_2\text{O}
\]

The name alkaloid means “like an alkali.” Thus, an alkaloid reacts with acid. The free compound can be recovered after extraction by reaction with a base:

\[
[R_3NH^+] \text{Cl}^- + \text{OH}^- \rightarrow R_3\text{N} + \text{H}_2\text{O} + \text{Cl}^- 
\]

The structures of many naturally occurring alkaloids have profound physiological and psychotropic effects in humans. Examples of these drugs include nicotine, morphine, codeine, and heroin. The

[^1]: [http://cnx.org/content/m51194/1.4/](http://cnx.org/content/m51194/1.4/)
plant produces these substances, collectively called secondary plant compounds, as chemical defenses against the numerous pests that attempt to feed on the plant:

In these diagrams, as is common in representing structures of large organic compounds, carbon atoms in the rings and the hydrogen atoms bonded to them have been omitted for clarity. The solid wedges indicate bonds that extend out of the page. The dashed wedges indicate bonds that extend into the page. Notice that small changes to a part of the molecule change the properties of morphine, codeine, and heroin. Morphine, a strong narcotic used to relieve pain, contains two hydroxyl functional groups, located at the bottom of the molecule in this structural formula. Changing one of these hydroxyl groups to a methyl ether group forms codeine, a less potent drug used as a local anesthetic. If both hydroxyl groups are converted to esters of acetic acid, the powerfully addictive drug heroin results (Figure 3).
Figure 3: Poppies can be used in the production of opium, a plant latex that contains morphine from which other opiates, such as heroin, can be synthesized. (credit: Karen Roe)

Amides are molecules that contain nitrogen atoms connected to the carbon atom of a carbonyl group. Like amines, various nomenclature rules may be used to name amides, but all include use of the class-specific suffix -amide:
Amides can be produced when carboxylic acids react with amines or ammonia in a process called amidation. A water molecule is eliminated from the reaction, and the amide is formed from the remaining pieces of the carboxylic acid and the amine (note the similarity to formation of an ester from a carboxylic acid and an alcohol discussed in the previous section):

The reaction between amines and carboxylic acids to form amides is biologically important. It is through this reaction that amino acids (molecules containing both amine and carboxylic acid substituents) link together in a polymer to form proteins.

NOTE: Proteins are large biological molecules made up of long chains of smaller molecules called amino acids. Organisms rely on proteins for a variety of functions—proteins transport molecules across cell membranes, replicate DNA, and catalyze metabolic reactions, to name only a few of their functions. The properties of proteins are functions of the combination of amino acids that compose them and can vary greatly. Interactions between amino acid sequences in the chains of proteins result in the folding of the chain into specific, three-dimensional structures that determine the protein’s activity.

Amino acids are organic molecules that contain an amine functional group (-NH₂), a carboxylic acid functional group (-COOH), and a side chain (that is specific to each individual amino acid). Most living things build proteins from the same 20 different amino acids. Amino acids connect by the formation of a peptide bond, which is a covalent bond formed between two amino acids when the carboxylic acid group of one amino acid reacts with the amine group of the other amino acid. The formation of the bond results in the production of a molecule of water (in general, reactions that result in the production of water when two other molecules combine are referred to as condensation reactions). The resulting bond—between the carbonyl group carbon atom and the amine nitrogen atom is called a peptide link or peptide bond. Since each of the original amino acids has an unreacted group (one has an unreacted amine and the other an unreacted carboxylic acid),

http://cnx.org/content/m51194/1.4/
more peptide bonds can form to other amino acids, extending the structure. (Figure 4) A chain of connected amino acids is called a polypeptide. Proteins contain at least one long polypeptide chain.

![Figure 4](http://cnx.org/content/m51194/1.4/) This condensation reaction forms a dipeptide from two amino acids and leads to the formation of water.

Enzymes are large biological molecules, mostly composed of proteins, which are responsible for the thousands of metabolic processes that occur in living organisms. Enzymes are highly specific catalysts; they speed up the rates of certain reactions. Enzymes function by lowering the activation energy of the reaction they are catalyzing, which can dramatically increase the rate of the reaction. Most reactions catalyzed by enzymes have rates that are millions of times faster than the noncatalyzed version. Like all catalysts, enzymes are not consumed during the reactions that they catalyze. Enzymes do differ from other catalysts in how specific they are for their substrates (the molecules that an enzyme will convert into a different product). Each enzyme is only capable of speeding up one or a few very specific reactions or types of reactions. Since the function of enzymes is so specific, the lack or malfunctioning of an enzyme can lead to serious health consequences. One disease that is the result of an enzyme malfunction is phenylketonuria. In this disease, the enzyme that catalyzes the first step in the degradation of the amino acid phenylalanine is not functional (Figure 5). Untreated, this can lead to an accumulation of phenylalanine, which can lead to intellectual disabilities.
Figure 5: A computer rendering shows the three-dimensional structure of the enzyme phenylalanine hydroxylase. In the disease phenylketonuria, a defect in the shape of phenylalanine hydroxylase causes it to lose its function in breaking down phenylalanine.

NOTE: Kevlar (Figure 6) is a synthetic polymer made from two monomers 1,4-phenylene-diamine
and terephthaloyl chloride (Kevlar is a registered trademark of DuPont). Kevlar’s first commercial use was as a replacement for steel in racing tires. Kevlar is typically spun into ropes or fibers. The material has a high tensile strength-to-weight ratio (it is about 5 times stronger than an equal weight of steel), making it useful for many applications from bicycle tires to sails to body armor.

![Kevlar Polymer Structure](http://cnx.org/content/m51194/1.4/)

**Figure 6:** This illustration shows the formula for polymeric Kevlar.

The material owes much of its strength to hydrogen bonds between polymer chains (refer back to the chapter on intermolecular interactions). These bonds form between the carbonyl group oxygen atom (which has a partial negative charge due to oxygen’s electronegativity) on one monomer and the partially positively charged hydrogen atom in the N–H bond of an adjacent monomer in the polymer structure (see dashed line in Figure 7). There is additional strength derived from the interaction between the unhybridized $p$ orbitals in the six-membered rings, called aromatic stacking.
Figure 7: The diagram shows the polymer structure of Kevlar, with hydrogen bonds between polymer chains represented by dotted lines.

Kevlar may be best known as a component of body armor, combat helmets, and face masks. Since the 1980s, the US military has used Kevlar as a component of the PASGT (personal armor system for ground troops) helmet and vest. Kevlar is also used to protect armored fighting vehicles and aircraft carriers. Civilian applications include protective gear for emergency service personnel such as body armor for police officers and heat-resistant clothing for fire fighters. Kevlar based clothing is considerably lighter and thinner than equivalent gear made from other materials (Figure 8).
In addition to its better-known uses, Kevlar is also often used in cryogenics for its very low thermal conductivity (along with its high strength). Kevlar maintains its high strength when cooled to the temperature of liquid nitrogen (−196 °C).

The table here summarizes the structures discussed in this chapter:
1 Key Concepts and Summary

The addition of nitrogen into an organic framework leads to two families of molecules. Compounds containing a nitrogen atom bonded in a hydrocarbon framework are classified as amines. Compounds that have a nitrogen atom bonded to one side of a carbonyl group are classified as amides. Amines are a basic functional group. Amines and carboxylic acids can combine in a condensation reaction to form amides.

2 Chemistry End of Chapter Exercises

Exercise 1
Write the Lewis structures of both isomers with the formula C₂H₇N.

Exercise 2
What is the molecular structure about the nitrogen atom in trimethyl amine and in the trimethyl ammonium ion, (CH₃)₃NH⁺? What is the hybridization of the nitrogen atom in trimethyl amine and in the trimethyl ammonium ion?
Exercise 3
Write the two resonance structures for the pyridinium ion, C₅H₅NH⁺.

Exercise 4
(Solution on p. 15.)
Draw Lewis structures for pyridine and its conjugate acid, the pyridinium ion, C₅H₅NH⁺. What are the geometries and hybridizations about the nitrogen atoms in pyridine and in the pyridinium ion?

Exercise 5
Write the Lewis structures of all isomers with the formula C₃H₇ON that contain an amide linkage.

Exercise 6
(Solution on p. 15.)
Write two complete balanced equations for the following reaction, one using condensed formulas and one using Lewis structures.
Methyl amine is added to a solution of HCl.

Exercise 7
Write two complete, balanced equations for each of the following reactions, one using condensed formulas and one using Lewis structures.
Ethylammonium chloride is added to a solution of sodium hydroxide.

Exercise 8
(Solution on p. 15.)
Identify any carbon atoms that change hybridization and the change in hybridization during the reactions in .

Exercise 9
Identify any carbon atoms that change hybridization and the change in hybridization during the reactions in .

Exercise 10
(Solution on p. 15.)
Identify any carbon atoms that change hybridization and the change in hybridization during the reactions in .
Solutions to Exercises in this Module

Solution to Exercise (p. 13)
Trimethyl amine: trigonal pyramidal, $sp^3$; trimethyl ammonium ion: tetrahedral, $sp^3$

Solution to Exercise (p. 14)

\[
\begin{align*}
\text{pyridine, trigonal planar, } sp^2 & \quad \text{pyridinium ion, trigonal planar, } sp^2 \\
\end{align*}
\]

Solution to Exercise (p. 14)

\[
\text{CH}_3\text{NH}_2 + \text{H}_3\text{O}^+ \rightarrow \text{CH}_3\text{NH}_3^+ + \text{H}_2\text{O}
\]

Solution to Exercise (p. 14)

\[
\text{CH}_3\text{CH} = \text{CHCH}_3(sp^2) + \text{Cl} \rightarrow \text{CH}_3\text{CH(Cl)(Cl)CH}_3(sp^3);
\]

\[
2\text{C}_6\text{H}_6(sp^2) + 15\text{O}_2 \rightarrow 12\text{CO}_2(sp) + 6\text{H}_2\text{O}
\]

Solution to Exercise (p. 14)
the carbon in $\text{CO}_3^{2-}$, initially at $sp^2$, changes hybridization to $sp$ in $\text{CO}_2$

Glossary

Definition 8: amine
organic molecule in which a nitrogen atom is bonded to one or more alkyl group

Definition 8: amide
organic molecule that features a nitrogen atom connected to the carbon atom in a carbonyl group
