Chapter 1

Digestive System Module 1: Overview of the Digestive System

The function of the digestive system is to break down the foods you eat, release their nutrients, and absorb these nutrients into the body. Although the **small intestine is the workhorse of the system, where the majority of digestion occurs**, and where most of the released nutrients are absorbed into the blood or lymph, each of the digestive system organs makes a vital contribution to this process (Figure 1.1 (Components of the Digestive System)).

Components of the Digestive System

Figure 1.1: All digestive organs play integral roles in the life-sustaining process of digestion.
As is the case with all body systems, the digestive system does not work in isolation; it functions cooperatively with the other systems of the body. Consider for example, the interrelationship between the digestive and cardiovascular systems. Arteries supply the digestive organs with oxygen and processed nutrients, and veins drain the digestive tract. These intestinal veins, constituting the hepatic portal system, are unique; they do not return blood directly to the heart. Rather, this blood is diverted to the liver where its nutrients are re-loaded for processing before blood completes its circuit back to the heart. At the same time, the digestive system provides nutrients to the heart muscle and vascular tissue to support their functioning. The interrelationship of the digestive and endocrine systems is also critical. Hormones secreted by several endocrine glands, as well as endocrine cells of the pancreas, the stomach, and the small intestine, contribute to the control of digestion and nutrient metabolism. In turn, the digestive system provides the nutrients to fuel endocrine function. Table 1.1 gives a quick glimpse at how these other systems contribute to the functioning of the digestive system. **You should take notes on this table.**

Table 1.1

1.1 Digestive System Organs

The easiest way to understand the digestive system is to divide its organs into two main categories. The first group is the organs that make up the alimentary canal. These organs are part of the "tube" our food travels through from the mouth to the anus. Accessory digestive organs comprise the second group. Food never enters or passes through these organs, but they are critical for orchestrating the breakdown of food. Accessory digestive organs, despite their name, are critical to the function of the digestive system.

Available for free at Connexions <http://legacy.cnx.org/content/col11761/1.1>
CHAPTER 1. DIGESTIVE SYSTEM MODULE 1: OVERVIEW OF THE DIGESTIVE SYSTEM

1.1.1 Alimentary Canal Organs

Also called the gastrointestinal (GI) tract or gut, the **alimentary canal** (aliment- = “to nourish”) is a one-way tube about 25 feet in length. The main function of the organs of the alimentary canal is to nourish the body. This tube begins at the mouth and terminates at the anus. Between those two points, the canal is modified as the pharynx (throat), esophagus, stomach, and small and large intestines to fit the functional needs of the body. Both the mouth and anus are open to the external environment; thus, food and wastes within the alimentary canal are technically considered to be outside the body. Only through the process of absorption do the nutrients in food enter into and nourish the body’s “inner space.”

1.1.2 Accessory Structures

Each **accessory digestive organ** aids in the breakdown of food (Figure 1.2 (Layers of the Alimentary Canal)). The salivary glands, in the mouth, begin the chemical digestion of food. Once food products enter the small intestine, the gallbladder, liver, and pancreas release secretions—such as bile and enzymes—essential for digestion to continue. Together, these are called accessory organs because although they are important, food does not pass through them. You could not live without their vital contributions, and many significant diseases result from their malfunction.

1.2 Tissues of the Alimentary Canal

Throughout its length, the alimentary tract is composed of the same four tissue layers; the details of their structural arrangements vary to fit their specific functions. Starting from the lumen and moving outwards, these layers are the mucosa, submucosa, muscularis, and serosa, which is continuous with the mesentery (see Figure 1.2 (Layers of the Alimentary Canal)).
Layers of the Alimentary Canal

Figure 1.2: The wall of the alimentary canal has four basic tissue layers: the mucosa, submucosa, muscularis, and serosa.

The mucosa is referred to as a mucous membrane, because mucus production is a characteristic feature of this layer. The membrane consists of epithelium, which is in direct contact with ingested food. Epithelium—is a type of tissue, found in the mouth, stomach, intestines, pharynx, esophagus and anal canal. The beginning and end of tube is lined with of a type of epithelium called stratified squamous epithelium. The stomach and intestines are lined simple columnar epithelium. Notice that the epithelium is in direct contact with the space inside the alimentary canal called the lumen.

As its name implies, the submucosa lies immediately beneath the mucosa. It is composed of another tissue known as dense connective tissue. The mucosa is referred to as a mucous membrane, because mucus production is a characteristic feature of this layer. It includes blood and lymphatic vessels (which transport absorbed nutrients).

The third layer of the alimentary canal is the muscularis. The muscularis in the small intestine is made up of a double layer of smooth muscle. The contractions of these layers promote mechanical digestion, expose more of the food to digestive chemicals, and move the food along the canal.

The serosa is the outermost layer of the alimentary canal, superficial to the muscularis. Instead of serosa, the mouth, pharynx, and esophagus have a dense sheath of collagen fibers called the adventitia. These tissues serve to hold the alimentary canal in place near the ventral surface of the vertebral column.
CHAPTER 1. DIGESTIVE SYSTEM MODULE 1: OVERVIEW OF THE DIGESTIVE SYSTEM

1.3 Nerve Supply

As soon as food enters the mouth, it is detected by receptors that send impulses along the sensory neurons of cranial nerves. Without these nerves, not only would your food be without taste, but you would also be unable to feel either the food or the structures of your mouth, and you would be unable to avoid biting yourself as you chew, an action enabled by the motor branches of cranial nerves. In addition the nervous system controls the movement of food through the alimentary tube and controls the release of enzymes and hormones that are important in the digestion and absorption of food.

1.4 Blood Supply

The blood vessels serving the digestive system have two functions. They transport the protein and carbohydrate nutrients absorbed by cells after food is digested in the lumen. Lipids are absorbed via lacteals, tiny structures of the lymphatic system. The blood vessels’ second function is to supply the organs of the alimentary canal with the nutrients and oxygen needed to drive their cellular processes.

The veins that collect nutrient-rich blood from the small intestine (where most absorption occurs) empty into the hepatic portal system. This network takes the blood into the liver where the nutrients are either processed or stored for later use. Only then does the blood circulate back to the heart.

1.5 Chapter Review

The digestive system includes the organs of the alimentary canal and accessory structures. The alimentary canal forms a continuous tube that is open to the outside environment at both ends. The organs of the alimentary canal are the mouth, pharynx, esophagus, stomach, small intestine, and large intestine. The accessory digestive structures include the teeth, tongue, salivary glands, liver, pancreas, and gallbladder. The wall of the alimentary canal is composed of four basic tissue layers: mucosa, submucosa, muscularis, and serosa. The enteric nervous system provides intrinsic innervation, and the autonomic nervous system provides extrinsic innervation.

## Stomach

- Mixes and churns food with gastric juices to form chyme
- Begins chemical breakdown of proteins
- Releases food into the duodenum as chyme
- Absorbs some fat-soluble substances (for example, alcohol, aspirin)
- Possesses antimicrobial functions
- Stimulates protein-digesting enzymes
- Secretes intrinsic factor required for vitamin B₁₂ absorption in small intestine

## Small intestine

- Mixes chyme with digestive juices to further breakdown food
- Propels food at a rate slow enough for digestion and absorption
- Absorbs breakdown products of carbohydrates, proteins, lipids, and nucleic acids, along with vitamins, minerals, and water
- Performs physical digestion via segmentation
- Provides optimal medium for enzymatic activity

*continued on next page*
### Accessory organs

| Liver: produces bile salts, which emulsify lipids, aiding their digestion and absorption | Bicarbonate-rich pancreatic juices help neutralize acidic chyme and provide optimal environment for enzymatic activity |
| Gallbladder: stores, concentrates, and releases bile | |
| Pancreas: produces digestive enzymes and bicarbonate | |

### Large intestine

| Further breaks down food residues | Food residue is concentrated and temporarily stored prior to defecation |
| Absorbs most residual water, electrolytes, and vitamins produced by enteric bacteria | Mucus eases passage of feces through colon |
| Propels feces toward rectum | |
| Eliminates feces | |

**Table 2.1**

### 2.1 Digestive Processes

The processes of digestion include six activities: ingestion, propulsion, mechanical or physical digestion, chemical digestion, absorption, and defecation.

The first of these processes, **ingestion**, refers to the entry of food into the alimentary canal through the mouth. There, the food is chewed and mixed with saliva, which contains enzymes that begin breaking down the carbohydrates in the food. Chewing increases the surface area of the food and allows an appropriately sized **bolus** (ball of chewed food) to be produced.

Food leaves the mouth when the tongue and throat muscles propel it into the esophagus. This act of swallowing, the last voluntary act until defecation, is an example of **propulsion**, which refers to the movement of food through the digestive tract. It includes both the voluntary process of swallowing and the involuntary process of peristalsis. **Peristalsis** consists of sequential, alternating waves of contraction and relaxation of alimentary wall smooth muscles, which act to propel food along (Figure 2.1 (Peristalsis)). These waves also play a role in mixing food with digestive juices. Peristalsis is so powerful that foods and liquids you swallow enter your stomach even if you are standing on your head.

---

Available for free at Connexions <http://legacy.cnx.org/content/col11761/1.1>
PERISTALIS

Digestion includes both mechanical and chemical processes. Mechanical digestion is a purely physical process that does not change the chemical nature of the food. Instead, it makes the food smaller to increase both surface area and mobility. It includes mastication, or chewing, as well as tongue movements that help break food into smaller bits and mix food with saliva. Although there may be a tendency to think that mechanical digestion is limited to the first steps of the digestive process, it occurs after the food leaves the mouth, as well. The mechanical churning of food in the stomach serves to further break it apart and expose more of its surface area to digestive juices, creating an acidic “soup” called chyme. Segmentation, which occurs mainly in the small intestine, consists of localized contractions of circular muscle of the muscularis layer of the alimentary canal. These contractions move their contents back and forth while continuously subdividing, breaking up, and mixing the contents.

In chemical digestion, starting in the mouth, digestive secretions break down complex food molecules into their chemical building blocks (for example, proteins into separate amino acids). These secretions vary in composition, but typically contain water, various enzymes, acids, and salts. The process is completed in the small intestine.

Food that has been broken down is of no value to the body unless it enters the bloodstream and its nutrients are put to work. This occurs through the process of absorption, which takes place primarily within the small intestine. There, most nutrients are absorbed from the lumen of the alimentary canal into the bloodstream through the epithelial cells that make up the mucosa. Lipids are absorbed into lacteals and are transported via the lymphatic vessels to the bloodstream. Remember that digestion and absorption are different processes. The details of these processes will be discussed later.

In defecation, the final step in digestion, undigested materials are removed from the body as feces.

In some cases, a single organ is in charge of a digestive process. For example, ingestion occurs only in the mouth and defecation only in the anus. However, most digestive processes involve the interaction of several organs and occur gradually as food moves through the alimentary canal (Figure 2.2 (Digestive Processes)).

Available for free at Connexions <http://legacy.cnx.org/content/col11761/1.1>
Figure 2.2: The digestive processes are ingestion, propulsion, mechanical digestion, chemical digestion, absorption, and defecation.

Some chemical digestion occurs in the mouth. Some absorption can occur in the mouth and stomach, for example, alcohol and aspirin.
CHAPTER 2. DIGESTIVE SYSTEM MODULE 2: PROCESSES AND REGULATION

2.2 Regulatory Mechanisms

The nervous and endocrine systems mechanisms work to maintain the optimal conditions in the lumen needed for digestion and absorption. These regulatory mechanisms, which stimulate digestive activity through mechanical and chemical activity.

2.2.1 Neural Controls

The walls of the alimentary canal contain a variety of sensors that help regulate digestive functions. For example, these receptors can sense when the presence of food has caused the stomach to expand, whether food particles have been sufficiently broken down, how much liquid is present, and the type of nutrients in the food (lipids, carbohydrates, and/or proteins). Another example is that the sight, smell, and taste of food initiate long reflexes that begin with a sensory neuron delivering a signal to the brain. The signal stimulates cells in the stomach to begin secreting digestive juices in preparation for incoming food.

2.2.2 Hormonal Controls

A variety of hormones are involved in the digestive process. The main digestive hormone of the stomach is gastrin, which is secreted in response to the presence of food. **Gastrin** stimulates the secretion of gastric acid by the parietal cells of the stomach. Other GI hormones are produced and act upon the gut and its accessory organs. Hormones produced by the duodenum include **secretin**, which stimulates a watery secretion of bicarbonate by the pancreas; **cholecystokinin (CCK)**, which stimulates the secretion of pancreatic enzymes and bile from the liver and release of bile from the gallbladder; and **gastric inhibitory peptide**, which slows gastric secretion and gastric emptying. These GI hormones are secreted by specialized epithelial cells, called endocrinocytes, located in the lining of the stomach and small intestine. These hormones then enter the, through the bloodstream which they can reach their target organs.

2.3 Chapter Review

The digestive system ingests and digests food, absorbs released nutrients, and excretes food components that are indigestible. The six activities involved in this process are ingestion, motility, mechanical digestion, chemical digestion, absorption, and defecation. These processes are regulated by neural and hormonal mechanisms.
Chapter 3

Digestive System Module 3: The Mouth, Pharynx, and Esophagus¹

In this section, you will examine the anatomy and functions of the three main organs of the upper alimentary canal—the mouth, pharynx, and esophagus—as well as three associated accessory organs—the tongue, salivary glands, and teeth.

3.1 The Mouth

The cheeks, tongue, and palate frame the mouth, which is also called the oral cavity (or buccal cavity). The structures of the mouth are illustrated in Figure 3.1 (Mouth).

At the entrance to the mouth are the lips, or labia (singular = labium). The lips cover the orbicularis oris muscle, which regulates what comes in and goes out of the mouth. The cheeks make up the oral cavity’s sidewalls. The next time you eat some food, notice how the muscles in your cheeks and the orbicularis oris muscle in your lips contract, helping you keep the food from falling out of your mouth.

When you are chewing, you do not find it difficult to breathe simultaneously. The next time you have food in your mouth, notice how the arched shape of the roof of your mouth allows you to handle both digestion and respiration at the same time. This arch is called the palate. The anterior region of the palate serves as a wall (or septum) between the oral and nasal cavities as well as a rigid shelf against which the tongue can push food. It is created by bones of the skull and, given its bony structure, is known as the hard palate. If you run your tongue along the roof of your mouth, you’ll notice that the hard palate ends in the posterior oral cavity, and the tissue becomes fleshier. This part of the palate, known as the soft palate, is composed mainly of skeletal muscle. You can therefore manipulate, subconsciously, the soft palate—for instance, to yawn, swallow, or sing (see Figure 3.1 (Mouth)).

¹This content is available online at <http://legacy.cnx.org/content/m49283/1.1/>.

Available for free at Connexions <http://legacy.cnx.org/content/col11761/1.1>
A fleshy bead of tissue called the uvula drops down from the center of the posterior edge of the soft palate. It serves an important purpose. When you swallow, the soft palate and uvula move upward, helping to keep foods and liquid from entering the nasal cavity. Unfortunately, it can also contribute to the sound produced by snoring.

Available for free at Connexions <http://legacy.cnx.org/content/col11761/1.1>
3.2 The Tongue

Perhaps you have heard it said that the tongue is the strongest muscle in the body. Those who stake this claim cite its strength proportionate to its size. Although it is difficult to quantify the relative strength of different muscles, it remains indisputable that the tongue is a workhorse, facilitating ingestion, mechanical digestion, sensation (of taste, texture, and temperature of food), swallowing, and vocalization. Working in concert, the muscles of the tongue perform three important digestive functions in the mouth: (1) position food for optimal chewing, (2) gather food into a bolus (rounded mass), and (3) position food so it can be swallowed.

3.3 The Salivary Glands

Many small salivary glands are housed within the mouth. These minor exocrine glands are constantly secreting saliva, either directly into the oral cavity or indirectly through ducts, even while you sleep. In fact, an average of 1 to 1.5 liters of saliva is secreted each day. Usually just enough saliva is present to moisten the mouth and teeth. Secretion increases when you eat, because saliva is essential to moisten food and initiate the chemical breakdown of carbohydrates.

3.3.1 The Major Salivary Glands

Outside the oral mucosa are three pairs of major salivary glands, which secrete the majority of saliva into ducts that open into the mouth:

- The submandibular glands, which are in the floor of the mouth, secrete saliva into the mouth through the submandibular ducts.
- The sublingual glands, which lie below the tongue, use the lesser sublingual ducts to secrete saliva into the oral cavity.
- The parotid glands lie between the skin and the masseter muscle, near the ears. They secrete saliva into the mouth through the parotid duct, which is located near the second upper molar tooth (Figure 3.2 (Salivary glands)).

3.3.2 Saliva

Saliva is essentially (95.5 percent) water. The remaining 4.5 percent is a complex mixture of ions, glycoproteins, enzymes, growth factors, and waste products. Perhaps the most important ingredient in saliva from the perspective of digestion is the enzyme salivary amylase, which initiates the breakdown of carbohydrates. Food does not spend enough time in the mouth to allow all the carbohydrates to break down, but salivary amylase continues acting until it is inactivated by stomach acids. Salivary mucus helps lubricate food, facilitating movement in the mouth, bolus formation, and swallowing.

Each of the major salivary glands secretes a unique formulation of saliva according to its cellular makeup. For example, the parotid glands secrete a watery solution that contains salivary amylase. The submandibular glands have cells similar to those of the parotid glands, as well as mucus-secreting cells. Therefore, saliva secreted by the submandibular glands also contains amylase but in a liquid thickened with mucus. The sublingual glands contain mostly mucous cells, and they secrete the thickest saliva with the least amount of salivary amylase.
3.4 The Teeth

The teeth, or dentes (singular = dens), are organs similar to bones that you use to tear, grind, and otherwise mechanically break down food.

3.4.1 Types of Teeth

During the course of your lifetime, you have two sets of teeth (one set of teeth is a dentition). Your 20 deciduous teeth, or baby teeth, first begin to appear at about 6 months of age. Between approximately age 6 and 12, these teeth are replaced by 32 permanent teeth. Moving from the center of the mouth toward the side, these are as follows (Figure 3.3 (Permanent and Deciduous Teeth )):

- The eight incisors, four top and four bottom, are the sharp front teeth you use for biting into food.
- The four cuspid (or canines) flank the incisors and have a pointed edge (cusp) to tear up food. These fang-like teeth are superb for piercing tough or fleshy foods.
- Posterior to the cuspid are the eight premolars (or bicuspid), which have an overall flatter shape with two rounded cusps useful for mashing foods.
The most posterior and largest are the 12 **molars**, which have several pointed cusps used to crush food so it is ready for swallowing. The third members of each set of three molars, top and bottom, are commonly referred to as the wisdom teeth, because their eruption is commonly delayed until early adulthood. It is not uncommon for wisdom teeth to fail to erupt; that is, they remain impacted. In these cases, the teeth are typically removed by orthodontic surgery.
Permanent and Deciduous Teeth

Permanent Teeth:
- Central incisor (7–8 yr)
- Lateral incisor (8–9 yr)
- Cusp or canine (11–12 yr)
- First premolar or bicusp (9–10 yr)
- Second premolar or bicusp (10–12 yr)
- First molar (6–7 yr)
- Second molar (12–13 yr)
- Third molar or wisdom tooth

Deciduous Teeth:
- Central incisor (9–12 mo)
- Lateral incisor (12–24 mo)
- Cusp or canine (16–24 mo)
- First molar (12–16 mo)
- Second molar (24–32 mo)
- Second molar (24–32 mo)
- First molar (12–16 mo)
- Cusp or canine (16–24 mo)
- Lateral incisor (12–15 mo)

Figure 3.3: The figure of two human dentitions shows the arrangement of teeth in the maxilla and mandible, and the relationship between the deciduous and permanent teeth.

Available for free at Connexions [http://legacy.cnx.org/content/col11761/1.1]
3.4.2 Anatomy of a Tooth

The teeth are secured in the alveolar processes (sockets) of the maxilla and the mandible. Gingivae (commonly called the gums) are soft tissues that line the alveolar processes and surround the necks of the teeth. Teeth are also held in their sockets by a connective tissue called the periodontal ligament.

The two main parts of a tooth are the crown, which is the portion projecting above the gum line, and the root, which is embedded within the maxilla and mandible. Both parts contain an inner pulp cavity, containing loose connective tissue through which run nerves and blood vessels. The region of the pulp cavity that runs through the root of the tooth is called the root canal. Surrounding the pulp cavity is dentin, a bone-like tissue. In the root of each tooth, the dentin is covered by an even harder bone-like layer called cementum. In the crown of each tooth, the dentin is covered by an outer layer of enamel, the hardest substance in the body (Figure 3.4 (The Structure of the Tooth)).

Although enamel protects the underlying dentin and pulp cavity, it is still nonetheless susceptible to mechanical and chemical erosion, or what is known as tooth decay. The most common form, dental caries (cavities) develops when colonies of bacteria feeding on sugars in the mouth release acids that cause soft tissue inflammation and degradation of the calcium crystals of the enamel. The digestive functions of the mouth are summarized in .

---

**The Structure of the Tooth**

![Diagram of Tooth Structure](http://legacy.cnx.org/content/col11761/1.1)

**Figure 3.4:** This longitudinal section through a molar in its alveolar socket shows the relationships between enamel, dentin, and pulp.

Available for free at Connexions [http://legacy.cnx.org/content/col11761/1.1]
3.5 The Pharynx

The pharynx (throat) is involved in both digestion and respiration. It receives food and air from the mouth, and air from the nasal cavities. When food enters the pharynx, involuntary muscle contractions close off the air passageways.

A short tube of skeletal muscle lined with a mucous membrane, the pharynx runs from the posterior oral and nasal cavities to the opening of the esophagus and larynx. It has three subdivisions. The most superior, the nasopharynx, is involved only in breathing and speech. The other two subdivisions, the oropharynx and the laryngopharynx, are used for both breathing and digestion. The oropharynx begins inferior to the nasopharynx and is continuous below with the laryngopharynx (Figure 3.5 (Pharynx)). The inferior border of the laryngopharynx connects to the esophagus, whereas the anterior portion connects to the larynx, allowing air to flow into the bronchial tree.
Figure 3.5: The pharynx runs from the nostrils to the esophagus and the larynx.

Usually during swallowing, the soft palate and uvula rise to close off the entrance to the nasopharynx. At the same time, epiglottis, folds inferiorly, covering the glottis (the opening to the larynx); this process effectively blocks access to the trachea and bronchi. When the food “goes down the wrong way,” it goes into the trachea. When food enters the trachea, the reaction is to cough, which usually forces the food up and out of the trachea, and back into the pharynx.

Available for free at Connexions <http://legacy.cnx.org/content/col11761/1.1>
CHAPTER 3. DIGESTIVE SYSTEM MODULE 3: THE MOUTH, PHARYNX, AND ESOPHAGUS

3.6 The Esophagus

The esophagus is a muscular tube that connects the pharynx to the stomach. It is approximately 25.4 cm (10 in) in length, located posterior to the trachea, and remains in a collapsed form when not engaged in swallowing. As you can see in Figure 3.6 (Esophagus), the esophagus runs a mainly straight route through the mediastinum of the thorax. To enter the abdomen, the esophagus penetrates the diaphragm through an opening called the esophageal hiatus.

3.6.1 Passage of Food through the Esophagus

The upper esophageal sphincter, controls the movement of food from the pharynx into the esophagus. Rhythmic waves of peristalsis, which begin in the upper esophagus, propel the bolus of food toward the stomach. Meanwhile, secretions from the esophagus lubricate the esophagus and food. Food passes from the esophagus into the stomach at the lower esophageal sphincter (also called the gastroesophageal or cardiac sphincter). Recall that sphincters are muscles that surround tubes and serve as valves, closing the tube when the sphincters contract and opening it when they relax. The lower esophageal sphincter relaxes to let food pass into the stomach, and then contracts to prevent stomach acids from backing up into the esophagus. When the lower esophageal sphincter does not completely close, the stomach’s contents can reflux (that is, back up into the esophagus), causing heartburn or gastroesophageal reflux disease (GERD).
Figure 3.6: The upper esophageal sphincter controls the movement of food from the pharynx to the esophagus. The lower esophageal sphincter controls the movement of food from the esophagus to the stomach.

3.7 Deglutition

Deglutition is another word for swallowing—the movement of food from the mouth to the stomach. The entire process takes about 4 to 8 seconds for solid or semisolid food, and about 1 second for very soft food.
and liquids. Although this sounds quick and effortless, deglutition is, in fact, a complex process that involves both the skeletal muscle of the tongue and the muscles of the pharynx and esophagus. It is aided by the presence of mucus and saliva. There are three stages in deglutition: the voluntary phase, the pharyngeal phase, and the esophageal phase (Figure 3.7 (Deglutition)).

![Deglutition](image)

**Figure 3.7:** Deglutition includes the voluntary phase and two involuntary phases: the pharyngeal phase and the esophageal phase.

### 3.8 Chapter Review

In the mouth, the tongue and the teeth begin mechanical digestion, and saliva begins chemical digestion. The pharynx, which plays roles in breathing and vocalization as well as digestion, runs from the nasal and oral cavities superiorly to the esophagus inferiorly (for digestion) and to the larynx anteriorly (for respiration). During deglutition (swallowing), the soft palate rises to close off the nasopharynx, the larynx elevates, and the epiglottis folds over the glottis. The esophagus includes an upper esophageal sphincter made of skeletal muscle, which regulates the movement of food from the pharynx to the esophagus. It also has a lower esophageal sphincter, made of smooth muscle, which controls the passage of food from the esophagus to the stomach. Cells in the esophageal wall secrete mucus that eases the passage of the food bolus.

Chapter 4

Digestive System Module 4: The Stomach

Chemical digestion really gets underway in the stomach. It lies immediately inferior to the esophagus, the stomach links the esophagus to the first part of the small intestine (the duodenum). It can be a highly active structure, contracting and continually changing position and size. These contractions provide mechanical assistance to digestion. The empty stomach is only about the size of your fist, but can stretch to hold as much as 4 liters of food and fluid, or more than 75 times its empty volume, and then return to its resting size when empty.

Popular culture tends to refer to the stomach as the location where all digestion takes place. Of course, this is not true. An important function of the stomach is to serve as a temporary holding chamber. You can ingest a meal far more quickly than it can be digested and absorbed by the small intestine. Thus, the stomach holds food and delivers only small amounts into the small intestine at a time. Foods are not processed in the order they are eaten; rather, they are mixed together with digestive juices in the stomach until they are converted into chyme, which is released into the small intestine.

As you will see in the sections that follow, the stomach plays several important roles in chemical digestion, including the continued digestion of carbohydrates and the initial digestion of proteins and fats. Little if any nutrient absorption occurs in the stomach, with the exception of the negligible amount of nutrients in alcohol.

4.1 Structure

There are four main regions in the stomach: the cardia, fundus, body, and pylorus (Figure 4.1 (Stomach)). The cardia (or cardiac region) is the point where the esophagus connects to the stomach and through which food passes into the stomach. Located inferior to the diaphragm, above and to the left of the cardia, is the dome-shaped fundus. Below the fundus is the body, the main part of the stomach. The funnel-shaped pylorus connects the stomach to the duodenum. connects to the body of the stomach. The narrower end is called the pyloric canal, which connects to the duodenum. The smooth muscle pyloric sphincter is located at this latter point of connection and controls stomach emptying. In the absence of food, the stomach deflates inward, and its mucosa falls into large folds called rugae.

1This content is available online at <http://legacy.cnx.org/content/m49286/1.2/>.
The convex lateral surface of the stomach is called the greater curvature; the concave medial border is the lesser curvature. The stomach is held in place by the lesser omentum, which extends from the liver to the lesser curvature, and the greater omentum, which runs from the greater curvature to the posterior abdominal wall.

4.2 Histology

The wall of the stomach is made of the same four layers as most of the rest of the alimentary canal, but with adaptations to the mucosa and muscularis for the unique functions of this organ. In addition to the typical circular and longitudinal smooth muscle layers, the muscularis has a third layer of muscle, the oblique muscle layer (Figure 4.2 (Histology of the Stomach)) which allows the stomach to vigorously churn food, mechanically breaking it down into smaller particles.
The stomach mucosa’s epithelial lining consists only of surface mucus cells, which secrete a protective coat of alkaline mucus. A vast number of gastric pits dot the surface of the epithelium, giving it the appearance of a well-used pincushion, and mark the entry to each gastric gland, which secretes a complex digestive fluid referred to as gastric juice.

Although the walls of the gastric pits are made up primarily of mucus cells, the gastric glands also include chief cells and parietal cells. Cells that make up the area of the pylorus secrete mucus and a number of hormones, including the majority of the stimulatory hormone, gastrin. The much larger glands of the fundus and body of the stomach, the site of most chemical digestion, produce most of the gastric secretions. These glands are made up of a variety of secretory cells. These include parietal cells, chief cells, mucus neck cells, and enteroendocrine cells.

Parietal cells—Located primarily in the middle region of the gastric glands are parietal cells which produce both hydrochloric acid (HCl) and intrinsic factor. HCl is responsible for the high acidity (pH 1.5 to 3.5) of the stomach contents and is needed to activate the protein-digesting enzyme, pepsin. The acidity also kills much of the bacteria you ingest with food and helps to break down proteins, making them more available for enzymatic digestion. Intrinsic factor is a glycoprotein necessary for the absorption of vitamin B_{12} in the small intestine.

Chief cells—Also located primarily in the gastric glands are chief cells, which secrete pepsinogen, the inactive substance that will convert to pepsin. HCl is necessary for the conversion of pepsinogen to pepsin.

Enteroendocrine cells—Finally, enteroendocrine cells which are also found in the gastric glands secrete various hormones. Do not take notes on table below.

Table 4.1 describes the digestive functions of important hormones secreted by the stomach.

4.3 Gastric Secretion

The secretion of gastric juice is controlled by both nerves and hormones. Stimuli in the brain, stomach, and small intestine activate or inhibit gastric juice production. This is why the three phases of gastric secretion are called the cephalic, gastric, and intestinal phases. However, once gastric secretion begins, all three phases can occur simultaneously. The cephalic phase (reflex phase) of gastric secretion, which is relatively brief, takes place before food enters the stomach. The smell, taste, sight, or thought of food triggers this phase. The gastric phase of secretion lasts 3 to 4 hours, and is set in motion by local neural and hormonal mechanisms triggered by the entry of food into the stomach. The intestinal phase of gastric secretion has a major role in regulating the emptying of the stomach into the small intestine.

4.4 The Mucosal Barrier

The mucosa of the stomach is exposed to the highly corrosive acidity of gastric juice. Gastric enzymes that can digest protein can also digest the stomach itself. The stomach is protected from self-digestion by the mucosal barrier. This barrier has several components. First, the stomach wall is covered by a thick coating of bicarbonate-rich mucus. This mucus forms a physical barrier, and its bicarbonate ions neutralize acid. Stem cells quickly produce new stomach cells. In fact, the surface epithelium of the stomach is completely replaced every 3 to 6 days.

4.5 Digestive Functions of the Stomach

4.5.1 Mechanical Digestion

Within a few moments after food after enters your stomach, mixing waves begin to occur at intervals of approximately 20 seconds. A mixing wave is a unique type of peristalsis that mixes and softens the food with gastric juices to create chyme. The pylorus acts as a filter, permitting only liquids and small food particles to pass through pyloric sphincter in a process called gastric emptying.

Gastric emptying is regulated by both the stomach and the duodenum. The presence of chyme in the duodenum activates receptors that inhibit gastric secretion. This prevents additional chyme from being released by the stomach before the duodenum is ready to process it.

4.5.2 Chemical Digestion

The fundus plays an important role, because it stores both undigested food and gases that are released during the process of chemical digestion. Food may sit in the fundus of the stomach for a while before being mixed with the chyme. While the food is in the fundus, the digestive activities of salivary amylase continue until the food begins mixing with the acidic chyme. Ultimately, mixing waves incorporate this food with the chyme, the acidity of which inactivates salivary amylase. Its numerous digestive functions notwithstanding, there is only one stomach function necessary to life: the production of intrinsic factor. The intestinal absorption of vitamin B₁₂, which is necessary for both the production of mature red blood cells and normal neurological functioning, cannot occur without intrinsic factor.

Available for free at Connexions <http://legacy.cnx.org/content/col11761/1.1>
The contents of the stomach are completely emptied into the duodenum within 2 to 4 hours after you eat a meal. Different types of food take different amounts of time to process. Foods heavy in carbohydrates empty fastest, followed by high-protein foods. Meals with a high fat content remain in the stomach the longest. Since enzymes in the small intestine digest fats slowly, food can stay in the stomach for 6 hours or longer when the duodenum is processing fatty chyme. However, note that this is still a fraction of the 24 to 72 hours that full digestion typically takes from start to finish.

4.6 Chapter Review

The stomach participates in all digestive activities except ingestion and defecation. It vigorously churns food. It secretes gastric juices that break down food and absorbs certain drugs, including aspirin and some alcohol. The stomach begins the digestion of protein and continues the digestion of carbohydrates and fats. It stores food as an acidic liquid called chyme, and releases it gradually into the small intestine through the pyloric sphincter.
Chapter 5

Digestive System Module 5: The Small and Large Intestines

The word intestine is derived from a Latin root meaning “internal,” and indeed, the two organs together nearly fill the interior of the abdominal cavity. In addition, called the small and large bowels, or colloquially the “guts,” they constitute the greatest mass and length of the alimentary canal and, with the exception of ingestion, perform all digestive system functions.

5.1 The Small Intestine

Chyme released from the stomach enters the small intestine, which is the primary digestive organ in the body. Not only is this where most digestion occurs, it is also where practically all absorption occurs. The longest part of the alimentary canal, the small intestine is about 10 feet long in a living person. Since this makes it about five times longer than the large intestine, you might wonder why it is called “small.” In fact, its name derives from its relatively smaller diameter of only about 1 inch, compared with 3 inch for the large intestine. As we’ll see shortly, in addition to its length, the folds and projections of the lining of the small intestine work to give it an enormous surface area, which is approximately 200 m$^2$, more than 100 times the surface area of your skin. This large surface area is necessary for complex processes of digestion and absorption that occur within it.

5.1.1 Structure

The coiled tube of the small intestine is subdivided into three regions. From the stomach to large intestine, these are the duodenum, jejunum, and ileum (Figure 5.1 (Small Intestine)).

The shortest region is the 10 inch duodenum, which begins at the pyloric sphincter. Just past the pyloric sphincter is the duodenal papilla. Located in the duodenal wall, it is where the bile duct (through which bile passes from the liver) and the main pancreatic duct (through which pancreatic juice passes from the pancreas) join the duodenum. The sphincter of Oddi regulates the flow of both bile and pancreatic juice from the papilla into the duodenum. The second part of the small intestine, the jejunum is about 3 feet long and runs from the duodenum to the ileum. The ileum is the longest part of the small intestine, measuring about 6 feet in length. The ileum joins the cecum, the first portion of the large intestine, at the ileocecal sphincter (or valve). The large intestine frames these three parts of the small intestine.

1This content is available online at <http://legacy.cnx.org/content/m49292/1.1/>.
5.1.2 Histology

The wall of the small intestine is composed of the same four layers typically present in the alimentary system. However, three features of the mucosa and submucosa are unique. These features, which increase the absorptive surface area of the small intestine more than 600-fold, include circular folds, villi, and microvilli (Figure 5.2 (Histology of the Small Intestine)). These adaptations are most abundant in the first two-thirds of the small intestine, where the majority of absorption occurs.
5.1.2.1 Adaptations to Increase Surface Area

There are three structural adaptations to the small intestine that increase the amount of area for food to be absorbed. A **circular fold** is a deep ridge in the mucosa and submucosa. Beginning near the first part of the duodenum and ending near the middle of the ileum, these folds increase absorption. Their shape causes the chyme to spiral, rather than move in a straight line, through the small intestine. Spiraling slows the movement of chyme and provides the time needed for nutrients to be fully absorbed. Within the circular folds are small (0.5–1 mm long) hairlike projections called **villi** (singular = villus) that give the mucosa a furry texture. There are about 20 to 40 villi per square millimeter, increasing the surface area of the epithelium tremendously. **Microvilli** (singular = microvillus) are much smaller (1 μm) than villi. They are surface extensions of the plasma membrane of the mucosa’s epithelial cells. Although their small size
makes it difficult to see each microvillus, their combined microscopic appearance suggests a mass of bristles, which is termed the \textit{brush border}. There are an estimated 200 million microvilli per square millimeter of small intestine, greatly expanding the surface area of the plasma membrane and thus greatly enhancing absorption.

\subsection*{5.1.3 Mechanical Digestion in the Small Intestine}

The movement of intestinal smooth muscles includes both segmentation and a form of peristalsis called migrating motility complexes. The kind of peristaltic mixing waves seen in the stomach are not observed here.

The smooth muscle layer of the small intestine is responsible for \textit{segmentation}. If you could see into the small intestine when it was going through segmentation, it would look as if the contents were being shoved incrementally back and forth. It combines the chyme with digestive juices and pushes food particles against the intestinal wall to be absorbed.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{segmentation.png}
\caption{Segmentation separates chyme and then pushes it back together, mixing it and providing time for digestion and absorption.}
\end{figure}
5.1.4 Chemical Digestion in the Small Intestine

The digestion of proteins and carbohydrates, which partially occurs in the stomach, is completed in the small intestine with the aid of intestinal and pancreatic juices. Lipids arrive in the intestine largely undigested, so much of the focus here is on lipid digestion, which is facilitated by bile. Moreover, intestinal juice combines with pancreatic juice to provide a liquid medium that facilitates absorption. The intestine is also where most water is absorbed, via osmosis. The small intestine’s absorptive cells also produce digestive enzymes.

5.2 The Large Intestine

The large intestine is the terminal part of the alimentary canal. The primary function of this organ is to finish absorption of nutrients and water, synthesize certain vitamins, form feces, and eliminate feces from the body.

5.2.1 Structure

The large intestine runs from the appendix to the anus. It frames the small intestine on three sides. Despite its being about one-half as long as the small intestine, it is called large because it is more than twice the diameter of the small intestine, about 3 inches. The large intestine is subdivided into four main regions: the cecum, the colon, the rectum, and the anus. The ileocecal valve, located at the opening between the ileum and the large intestine, controls the flow of chyme from the small intestine to the large intestine.

5.2.2 Subdivisions

5.2.2.1 Cecum

The first part of the large intestine is the cecum, a sac-like structure that is suspended inferior to the ileocecal valve. It is about 2.4 inches long, receives the contents of the ileum, and continues the absorption of water and salts. The appendix is a winding tube that attaches to the cecum. Although the 3-inch long appendix contains lymphoid tissue, suggesting an immune function, this organ is generally considered vestigial (no longer useful). However, at least one recent report suggests a survival advantage provided by the appendix: In illness, the appendix may serve as a bacterial reservoir to repopulate the bacteria after the illness.

5.2.2.2 Colon

The cecum blends seamlessly with the colon. Upon entering the colon, the food residue first travels up the ascending colon on the right side of the abdomen. At the inferior surface of the liver, the colon bends to form the right colic flexure (hepatic flexure) and becomes the transverse colon. Food residue passing through the transverse colon travels across to the left side of the abdomen, where the colon angles sharply immediately inferior to the spleen, at the left colic flexure (splenic flexure). From there, food residue passes through the descending colon, which runs down the left side of the abdominal wall. After entering the pelvis it becomes the s-shaped sigmoid colon.
5.2.3 Histology

There are several notable differences between the walls of the large and small intestines (Figure 5.5 (Histology of the large Intestine)). For example, few enzyme-secreting cells are found in the wall of the large intestine, and there are no circular folds or villi. There is an increased number of mucus producing goblet cells. These goblet cells secrete mucus that eases the movement of feces and protects the intestine.
5.2.4 Anatomy

Three features are unique to the large intestine: teniae coli, haustra, and epiploic appendages (Figure 5.6 (Teniae Coli, Haustra, and Epiploic Appendages)). The teniae coli are three bands of smooth muscle that make up the longitudinal muscle layer of the muscularis of the large intestine, except at its terminal end. Tonic contractions of the teniae coli bunch up the colon into a succession of pouches called haustra (singular = hostrum), which are responsible for the wrinkled appearance of the colon. Attached to the teniae coli are small, fat-filled sacs of visceral peritoneum called epiploic appendages. The purpose of these is unknown.
Although the rectum and anal canal have neither teniae coli nor haustra, they do have well-developed layers of muscularis that create the strong contractions needed for defecation.

### Teniae Coli, Haustra, and Epiploic Appendages

![Diagram of Teniae Coli, Haustra, and Epiploic Appendages](image)

**Figure 5.6**

### 5.2.5 Bacterial Flora

Most bacteria that enter the alimentary canal are killed by lysozyme, HCl, or protein-digesting enzymes. However, trillions of bacteria live within the large intestine and are referred to as the bacterial flora. Most of the more than 700 species of these bacteria cause no harm as long as they stay in the gut lumen. In fact, many facilitate chemical digestion and absorption.
5.2.6 Digestive Functions of the Large Intestine

The residue of chyme that enters the large intestine contains few nutrients except water, which is reabsorbed as the residue lingers in the large intestine, typically for 12 to 24 hours. Thus, it may not surprise you that the large intestine can be completely removed without significantly affecting digestive functioning. For example, in severe cases of inflammatory bowel disease, the large intestine can be removed by a procedure known as a colectomy. Often, a new fecal pouch can be crafted from the small intestine and sutured to the anus, but if not, an ileostomy can be created by bringing the distal ileum through the abdominal wall, allowing the watery chyme to be collected in a bag-like adhesive appliance.

5.2.7 Absorption, Feces Formation, and Defecation

The small intestine absorbs about 90 percent of the water you ingest (either as liquid or within solid food). The large intestine absorbs most of the remaining water, a process that converts the liquid chyme residue into semisolid feces (“stool”). Feces is composed of undigested food residues, unabsorbed digested substances, millions of bacteria, old epithelial cells from the GI mucosa, inorganic salts, and enough water to let it pass smoothly out of the body. Of every 500 mL (17 ounces) of food residue that enters the cecum each day, about 150 mL (5 ounces) become feces.

Feces are eliminated through contractions of the rectal muscles. You help this process by a voluntary procedure called Valsalva’s maneuver, in which you increase intra-abdominal pressure by contracting your diaphragm and abdominal wall muscles, and closing your glottis.

If defecation is delayed for an extended time, additional water is absorbed, making the feces firmer and potentially leading to constipation. On the other hand, if the waste matter moves too quickly through the intestines, not enough water is absorbed, and diarrhea can result. This can be caused by the ingestion of foodborne pathogens. In general, diet, health, and stress determine the frequency of bowel movements. The number of bowel movements varies greatly between individuals, ranging from two or three per day to three or four per week.

5.3 Chapter Review

The three main regions of the small intestine are the duodenum, the jejunum, and the ileum. The small intestine is where digestion is completed and virtually all absorption occurs. These two activities are facilitated by structural adaptations that increase the mucosal surface area by 600-fold, including circular folds, villi, and microvilli. There are around 200 million microvilli per square millimeter of small intestine, which contain brush border enzymes that complete the digestion of carbohydrates and proteins. Combined with pancreatic juice, intestinal juice provides the liquid medium needed to further digest and absorb substances from chyme. The small intestine is also the site of unique mechanical digestive movements. Segmentation moves the chyme back and forth, increasing mixing and opportunities for absorption. Migrating motility complexes propel the residual chyme toward the large intestine.

The main regions of the large intestine are the cecum, the colon, and the rectum. The large intestine absorbs water and forms feces, and is responsible for defecation. Bacterial flora break down additional carbohydrate residue, and synthesize certain vitamins. The mucosa of the large intestinal wall is generously endowed with goblet cells, which secrete mucus that eases the passage of feces. The entry of feces into the rectum activates the defecation reflex.

Chemical digestion in the small intestine relies on the activities of three accessory digestive organs: the liver, pancreas, and gallbladder (Figure 6.1 (Accessory Organs)). The digestive role of the liver is to produce bile and export it to the duodenum. The gallbladder primarily stores, concentrates, and releases bile. The pancreas produces pancreatic juice, which contains digestive enzymes and bicarbonate ions, and delivers it to the duodenum.

\footnote{This content is available online at \texttt{http://legacy.cnx.org/content/m49293/1.1/}.}
Accessory Organs

Figure 6.1: The liver, pancreas, and gallbladder are considered accessory digestive organs, but their roles in the digestive system are vital.
6.1 The Liver

The liver is the largest gland in the body, weighing about three pounds in an adult. It is also one of the most important organs. In addition to being an accessory digestive organ, it plays a number of roles in metabolism and regulation. The liver lies inferior to the diaphragm in the right upper quadrant of the abdominal cavity and receives protection from the surrounding ribs. The liver is divided into two primary lobes: a large right lobe and a much smaller left lobe. The liver is connected to the abdominal wall and diaphragm by five ligaments. The falciform ligament is visible on the midline of the surface of the liver.

The liver has two blood supplies. The first comes via the hepatic artery and brings fresh oxygenated blood to the liver, in the same way that oxygenated blood is supplied to all the body’s organs. The second blood supply is delivered via the hepatic portal vein. This vein is a major component of the hepatic portal system. This system brings blood containing recently absorbed nutrients from the small intestine. The liver monitors the blood coming from the small intestine. The liver will destroy toxins and other undesirable molecules before allowing the blood to return to the heart for distribution to the whole body.
Microscopic Anatomy of the Liver

**Figure 6.2:** The liver receives oxygenated blood from the hepatic artery and nutrient-rich deoxygenated blood from the hepatic portal vein.
6.1.1 Histology

A hepatocyte is the liver’s main cell type, accounting for around 80 percent of the liver’s volume. These cells play a role in a wide variety of secretory, metabolic, and endocrine functions. Between adjacent hepatocytes, bile manufactured by the liver accumulates and is directed to the right and left hepatic ducts, which merge to form the common hepatic duct which delivers bile to the gallbladder. This duct then joins with the cystic duct from the gallbladder, forming the common bile duct through which bile flows into the small intestine.

6.1.2 Bile

Recall that lipids do not dissolve in water. Thus, before they can be digested in the watery environment of the small intestine, large lipid globules must be broken down into smaller lipid globules, a process called emulsification. Bile is a mixture secreted by the liver to accomplish the emulsification of lipids in the small intestine. Hepatocytes secrete about one liter of bile each day. A yellow-brown or yellow-green solution, bile is a mixture of water, bile salts, bile pigments, cholesterol, and other molecules. The bile salts are most critical to emulsification. Emulsification results in the large lipid globules being pulled apart into many tiny lipid fragments. This change dramatically increases the surface area available for lipid-digesting enzyme activity. This is the same way dish soap works on fats mixed with water.

Hepatocytes work non-stop, but bile production increases when fatty chyme enters the duodenum and stimulates the secretion of the gut hormone secretin. Between meals, bile is produced but conserved. Bile is diverted to the gallbladder, where it is concentrated and stored until the next meal.

6.2 The Pancreas

The soft, oblong, glandular pancreas lies nestled into the “c-shaped” curvature of the duodenum with the body extending to the left. It is a curious mix of exocrine (secreting digestive enzymes) and endocrine (releasing hormones into the blood) functions (Figure 6.3 (Exocrine and Endocrine Pancreas)). The exocrine part of the pancreas arises as little grape-like cell clusters, each called an acinus (plural = acini), located at the terminal ends of pancreatic ducts. These acinar cells secrete enzyme-rich pancreatic juice into tiny merging ducts that form two dominant ducts. The larger duct fuses with the common bile duct (carrying bile from the liver and gallbladder) just before entering the duodenum via a common opening. Scattered through the sea of exocrine acini are small islands of endocrine cells, the islets of Langerhans. These vital cells produce the hormones insulin, glucagon, and other crucial hormones.

Available for free at Connexions <http://legacy.cnx.org/content/col11761/1.1>
6.2.1 Pancreatic Juice

The pancreas produces over a liter of pancreatic juice each day. Unlike bile, it is clear and composed mostly of water along with some salts, sodium bicarbonate, and several digestive enzymes. Sodium bicarbonate is responsible for the slight alkalinity of pancreatic juice, which serves to buffer the acidic gastric juice in chyme, inactivate pepsin from the stomach, and create an optimal environment for the activity of pH-sensitive digestive enzymes in the small intestine. Pancreatic enzymes are active in the digestion of sugars, proteins, and fats.

The pancreas produces protein-digesting enzymes in their inactive forms. These enzymes are activated in the duodenum. If produced in an active form, they would digest the pancreas (which is exactly what occurs in the disease, pancreatitis). The enzymes that digest starch (amylase), fat (lipase), and nucleic acids (nuclease) are secreted in their active forms, since they do not attack the pancreas as do the protein-digesting enzymes.

6.2.2 Pancreatic Secretion

Regulation of pancreatic secretion is the job of hormones. The entry of acidic chyme into the duodenum stimulates the release of the hormone secretin, which in turn causes the duct cells to release bicarbonate-rich pancreatic juice. The presence of proteins and fats in the duodenum stimulates the secretion of the hormone CCK, which then stimulates the acini to secrete enzyme-rich pancreatic juice and enhances the activity of secretin.

6.3 The Gallbladder

The gallbladder is 3–4 inches long and is nested in a shallow area on the posterior aspect of the right lobe of the liver. This muscular sac stores, concentrates, and, when stimulated, propels the bile into the duodenum via the common bile duct. The cystic duct is 1–2 cm (less than 1 in) long and merges with the hepatic duct coming from the liver. The gallbladder’s mucosa absorbs water and ions from bile, concentrating it by up to 10-fold and storing the bile until it is needed.
CHAPTER 6. DIGESTIVE SYSTEM MODULE 6: ACCESSORY ORGANS IN DIGESTION: THE LIVER, PANCREAS, AND GALLBLADDER

6.4 Chapter Review

Chemical digestion in the small intestine cannot occur without the help of the liver and pancreas. The liver produces bile and delivers it to the common hepatic duct. Bile contains bile salts and phospholipids, which emulsify large lipid globules into tiny lipid droplets, a necessary step in lipid digestion and absorption. The gallbladder stores and concentrates bile, releasing it when it is needed by the small intestine.

The pancreas produces the enzyme- and bicarbonate-rich pancreatic juice and delivers it to the small intestine through ducts. Pancreatic juice buffers the acidic gastric juice in chyme, inactivates pepsin from the stomach, and enables the optimal functioning of digestive enzymes in the small intestine.

Figure 6.4: The gallbladder stores and concentrates bile, and releases it into the two-way cystic duct when it is needed by the small intestine.
Chapter 7

Digestive System Module 7: Chemical Digestion and Absorption: A Closer Look

As you have learned, the process of mechanical digestion is relatively simple. It involves the physical breakdown of food but does not alter its chemical makeup. Chemical digestion, on the other hand, is a complex process that reduces food into its chemical building blocks, which are then absorbed to nourish the cells of the body (Figure 7.1 (Digestion and Absorption)). In this section, you will look more closely at the processes of chemical digestion and absorption.

1This content is available online at <http://legacy.cnx.org/content/m49457/1.1/>.

Available for free at Connexions <http://legacy.cnx.org/content/col11761/1.1>
7.1 Chemical Digestion

Large food molecules (for example, proteins, lipids, nucleic acids, and starches) must be broken down into subunits that are small enough to be absorbed by the lining of the alimentary canal. This is accomplished by enzymes.
7.1.1 Carbohydrate Digestion

The average American diet is about 50 percent carbohydrates, which may be classified according to the number of monomers (subunits) they contain. **You should take notes on figure 2 below.**

The chemical digestion of starches begins in the mouth and has been reviewed in previous modules. In the small intestine, **pancreatic amylase** does the ‘heavy lifting’ for starch and carbohydrate digestion (Figure 7.2 (Carbohydrate Digestion Flow Chart)). Amylases break down starches into simple sugars. Three brush border enzymes break up the sugars **sucrose, lactose, and maltose** into monosaccharides.

![Carbohydrate Digestion Flow Chart](https://example.com/flowchart.png)

**Figure 7.2:** Carbohydrates are broken down into their monomers in a series of steps.

7.1.2 Protein Digestion

Proteins are polymers composed of **amino acids** linked by peptide bonds to form long chains. Digestion reduces them to their constituent amino acids. You usually consume about 15 to 20 percent of your total calorie intake as protein.

The digestion of protein starts in the stomach, where **HCl** and **pepsin** break proteins into smaller subunits, which then travel to the small intestine (Figure 7.3 (Digestion of Protein)). Chemical digestion in the small intestine is continued by pancreatic enzymes, including **chymotrypsin** and **trypsin**, each of
which act on specific bonds in amino acid sequences. At the same time, the cells of the brush border secrete enzymes. This results in molecules small enough to enter the bloodstream (Figure 7.4 (Digestion of Protein Flow Chart)). Take notes on figure 4.

---

**Digestion of Protein**

- The liver regulates distribution of amino acids to the rest of the body.
- Absorbed amino acids enter the blood and travel to the liver.
- Protein digestion begins in the stomach by hydrochloric acid and the enzyme pepsin.
- Protein-digesting enzymes are secreted from the pancreas into the small intestine.
- The small intestine is the major site of protein digestion; final digestion occurs here.

**Figure 7.3:** The digestion of protein begins in the stomach and is completed in the small intestine.

7.1.3 Lipid Digestion

A healthy diet limits lipid intake to 35 percent of total calorie intake. The most common dietary lipids are triglycerides, which are made up of a glycerol molecule bound to three fatty acid chains. Small amounts of dietary cholesterol and phospholipids are also consumed.

The lipase primarily responsible for lipid digestion is \textit{pancreatic lipase}. However, because the pancreas is the only consequential source of lipase, virtually all lipid digestion occurs in the small intestine. Pancreatic lipase breaks down each triglyceride into subunits called \textit{free fatty acids} and \textit{monoglycerides}.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{protein_dig_flowchart}
\caption{Proteins are successively broken down into their amino acid components.}
\end{figure}
7.1.4 Nucleic Acid Digestion

The nucleic acids DNA and RNA are found in most of the foods you eat. Two types of pancreatic nuclease are responsible for their digestion. The nucleotides produced by this digestion are further broken down by two intestinal brush border enzymes so they be through the alimentary canal wall. The large food molecules that must be broken down into subunits are summarized Table 7.1

Table 7.1

7.2 Absorption

The mechanical and digestive processes have one goal: to convert food into molecules small enough to be absorbed by the epithelial cells of the intestinal villi. By the time chyme passes from the ileum into the large intestine, it is essentially indigestible food residue (mainly plant fibers like cellulose), some water, and millions of bacteria (Figure 7.5 (Digestive Secretions and Absorption of Water)).
Absorption can occur through several mechanisms: **active transport** to the movement of a substance across a cell membrane using cellular energy (ATP) to move the substance refers to an area of lower con-
centration to an area of higher concentration using cellular energy (ATP) to move the substance. Passive diffusion refers to the movement of substances from an area of higher concentration to an area of lower concentration.

7.2.1 Carbohydrate Absorption
All carbohydrates are absorbed in the form of monosaccharides. The small intestine is highly efficient at this, absorbing monosaccharides at an estimated rate of 120 grams per hour. All normally digested dietary carbohydrates are absorbed; indigestible fibers are eliminated in the feces.

7.2.2 Protein Absorption
Active transport mechanisms, primarily in the duodenum and jejunum, absorb most proteins as their breakdown products, amino acids. Almost all (95 to 98 percent) protein is digested and absorbed in the small intestine via diffusion.

7.2.3 Lipid Absorption
About 95 percent of lipids are absorbed in the small intestine. Bile salts not only speed up lipid digestion, they are also essential to the absorption of the end products of lipid digestion. The lipid subunits are too big to pass through the basement membranes of blood capillaries, instead they enter the large pores of lacteals. The lacteals come together to form the lymphatic vessels, the lymphatic vessels and are part of the lymphatic system.
7.2.4 Nucleic Acid Absorption

The products of nucleic acid digestion—pentose sugars, nitrogenous bases, and phosphate ions—are transported by carriers across the villus epithelium via active transport. These products then enter the bloodstream.
7.2.5 Water Absorption

Each day, about nine liters of fluid enter the small intestine. About 2.3 liters are ingested in foods and beverages, and the rest is from GI secretions. About 90 percent of this water is absorbed in the small intestine. Water absorption is driven by the concentration gradient of the water: The concentration of water is higher in chyme than it is in epithelial cells. Thus, water moves down its concentration gradient from the chyme into cells. As noted earlier, much of the remaining water is then absorbed in the colon.

7.3 Chapter Review

The small intestine is the site of most chemical digestion and almost all absorption. Chemical digestion breaks large food molecules down into their chemical building blocks, which can then be absorbed through the intestinal wall and into the general circulation. Intestinal brush border enzymes and pancreatic enzymes are responsible for the majority of chemical digestion. The breakdown of fat also requires bile.

Most nutrients are absorbed by transport mechanisms at the apical surface of enterocytes. Exceptions include lipids, fat-soluble vitamins, and most water-soluble vitamins. With the help of bile salts and lecithin, the dietary fats are emulsified to form micelles, which can carry the fat particles to the surface of the enterocytes. There, the micelles release their fats to diffuse across the cell membrane. The fats are then reassembled into triglycerides and mixed with other lipids and proteins into chylomicrons that can pass into lacteals. Other absorbed monomers travel from blood capillaries in the villus to the hepatic portal vein and then to the liver.
A absorption
   passage of digested products from the intestinal lumen through mucosal cells and into the bloodstream or lacteals

accessory digestive organ
   includes teeth, tongue, salivary glands, gallbladder, liver, and pancreas

accessory duct
   (also, duct of Santorini) duct that runs from the pancreas into the duodenum

acinus
   cluster of glandular epithelial cells in the pancreas that secretes pancreatic juice in the pancreas

alimentary canal
   continuous muscular digestive tube that extends from the mouth to the anus

aminopeptidase
   brush border enzyme that acts on proteins

anal canal
   final segment of the large intestine

anal column
   long fold of mucosa in the anal canal

anal sinus
   recess between anal columns

appendix
   (vermiform appendix) coiled tube attached to the cecum

ascending colon
   first region of the colon

B bacterial flora
   bacteria in the large intestine

bile
   alkaline solution produced by the liver and important for the emulsification of lipids

bile canaliculus
   small duct between hepatocytes that collects bile

bilirubin
   main bile pigment, which is responsible for the brown color of feces

body
   mid-portion of the stomach

bolus
   mass of chewed food

brush border
   fuzzy appearance of the small intestinal mucosa created by microvilli

C cardia
   (also, cardiac region) part of the stomach surrounding the cardiac orifice (esophageal hiatus)

cecum
   pouch forming the beginning of the large intestine

cementum
   bone-like tissue covering the root of a tooth

central vein
   vein that receives blood from hepatic sinusoids

cephalic phase
   (also, reflex phase) initial phase of gastric secretion that occurs before food enters the stomach

chemical digestion
   enzymatic breakdown of food

chief cell
   gastric gland cell that secretes pepsinogen

chylomicron
large lipid-transport compound made up of triglycerides, phospholipids, cholesterol, and proteins
dentition
set of teeth
deoxyribonuclease
pancreatic enzyme that digests DNA
descending colon
part of the colon between the transverse colon and the sigmoid colon
dipeptidase
brush border enzyme that acts on proteins
duodenal gland
(also, Brunner’s gland) mucous-secreting gland in the duodenal submucosa
duodenum
first part of the small intestine, which starts at the pyloric sphincter and ends at the jejunum
enamel
covering of the dentin of the crown of a tooth
enteroendocrine cell
gastric gland cell that releases hormones
enterohepatic circulation
recycling mechanism that conserves bile salts
enteropeptidase
intestinal brush-border enzyme that activates trypsinogen to trypsin
epiploic appendage
small sac of fat-filled visceral peritoneum attached to teniae coli
esophagus
muscular tube that runs from the pharynx to the stomach
external anal sphincter
voluntary skeletal muscle sphincter in the anal canal
fauces
opening between the oral cavity and the oropharynx
feces
semisolid waste product of digestion
flatus
GLOSSARY

gas in the intestine

findus
dome-shaped region of the stomach above and to the left of the cardia

G G cell
gastrin-secreting enteroendocrine cell

gallbladder
accessory digestive organ that stores and concentrates bile

gastric emptying
process by which mixing waves gradually cause the release of chyme into the duodenum

gastric gland
gland in the stomach mucosal epithelium that produces gastric juice

gastric phase
phase of gastric secretion that begins when food enters the stomach

gastric pit
narrow channel formed by the epithelial lining of the stomach mucosa

gastrin
peptide hormone that stimulates secretion of hydrochloric acid and gut motility

gastrocolic reflex
propulsive movement in the colon activated by the presence of food in the stomach

gastroileal reflex
long reflex that increases the strength of segmentation in the ileum

gingiva

gum

H haustral contraction
slow segmentation in the large intestine

haustrum
small pouch in the colon created by tonic contractions of teniae coli

hepatic artery
artery that supplies oxygenated blood to the liver

hepatic lobule
hexagonal-shaped structure composed of hepatocytes that radiate outward from a central vein

hepatic portal vein
vein that supplies deoxygenated nutrient-rich blood to the liver

hepatic sinusoid
blood capillaries between rows of hepatocytes that receive blood from the hepatic portal vein and the branches of the hepatic artery

hepatic vein
vein that drains into the inferior vena cava

hepatocytes
major functional cells of the liver

hepatopancreatic ampulla
(also, ampulla of Vater) bulb-like point in the wall of the duodenum where the bile duct and main pancreatic duct unite

hepatopancreatic sphincter
(also, sphincter of Oddi) sphincter regulating the flow of bile and pancreatic juice into the duodenum

hydrochloric acid (HCl)
digestive acid secreted by parietal cells in the stomach

I ileocecal sphincter
sphincter located where the small intestine joins with the large intestine

ileum
end of the small intestine between the jejunum and the large intestine

incisor
midline, chisel-shaped tooth used for cutting into food

ingestion
taking food into the GI tract through the mouth

internal anal sphincter
involuntary smooth muscle sphincter in the anal canal

**intestinal gland**
(also, crypt of Lieberkühn) gland in the small intestinal mucosa that secretes intestinal juice

**intestinal juice**
mixture of water and mucus that helps absorb nutrients from chyme

**intestinal phase**
phase of gastric secretion that begins when chyme enters the intestine

**intrinsic factor**
glycoprotein required for vitamin B₁₂ absorption in the small intestine

**Jejunum**
middle part of the small intestine between the duodenum and the ileum

**Labial frenulum**
midline mucous membrane fold that attaches the inner surface of the lips to the gums

**Labium**
lip

**Lactase**
brush border enzyme that breaks down lactose into glucose and galactose

**Lacteal**
lymphatic capillary in the villi

**Large intestine**
terminal portion of the alimentary canal

**Laryngopharynx**
part of the pharynx that functions in respiration and digestion

**Left colic flexure**
(also, splenic flexure) point where the transverse colon curves below the inferior end of the spleen

**Lingual frenulum**
mucous membrane fold that attaches the bottom of the tongue to the floor of the mouth

**Lingual lipase**
digestive enzyme from glands in the tongue that acts on triglycerides

**Lipoprotein lipase**
enzyme that breaks down triglycerides in chylomicrons into fatty acids and monoglycerides

**Liver**
largest gland in the body whose main digestive function is the production of bile

**Lower esophageal sphincter**
smooth muscle sphincter that regulates food movement from the esophagus to the stomach

**Main pancreatic duct**
(also, duct of Wirsung) duct through which pancreatic juice drains from the pancreas

**Major duodenal papilla**
point at which the hepatopancreatic ampulla opens into the duodenum

**Maltase**
brush border enzyme that breaks down maltose and maltotriose into two and three molecules of glucose, respectively

**Mass movement**
long, slow, peristaltic wave in the large intestine

**Mastication**
chewing

**Mechanical digestion**
chewing, mixing, and segmentation that prepares food for chemical digestion

**Mesoappendix**
mesentery of the appendix

**Micelle**
tiny lipid-transport compound composed of bile salts and phospholipids with a fatty acid and monoacylglyceride core

**Microvillus**
small projection of the plasma membrane of the absorptive cells of the small intestinal mucosa

Available for free at Connexions <http://legacy.cnx.org/content/col11761/1.1>
migrating motility complex
form of peristalsis in the small intestine

mixing wave
unique type of peristalsis that occurs in the stomach

molar
tooth used for crushing and grinding food

motilin
hormone that initiates migrating motility complexes

motility
movement of food through the GI tract

mucosa
innermost lining of the alimentary canal

mucosal barrier
protective barrier that prevents gastric juice from destroying the stomach itself

mucous neck cell
gastric gland cell that secretes a uniquely acidic mucus

muscularis
muscle (skeletal or smooth) layer of the alimentary canal wall

myenteric plexus
(plexus of Auerbach) major nerve supply to alimentary canal wall; controls motility

N nucleosidase
brush border enzyme that digests nucleotides

O oral cavity
(also, buccal cavity) mouth
oral vestibule
part of the mouth bounded externally by the cheeks and lips, and internally by the gums and teeth

oropharynx
part of the pharynx continuous with the oral cavity that functions in respiration and digestion

P palatoglossal arch
muscular fold that extends from the lateral side of the soft palate to the base of the tongue

palatopharyngeal arch
muscular fold that extends from the lateral side of the soft palate to the side of the pharynx

pancreas
accessory digestive organ that secretes pancreatic juice

pancreatic amylase
enzyme secreted by the pancreas that completes the chemical digestion of carbohydrates in the small intestine

pancreatic juice
secretion of the pancreas containing digestive enzymes and bicarbonate

pancreatic lipase
enzyme secreted by the pancreas that participates in lipid digestion

pancreatic nuclease
enzyme secreted by the pancreas that participates in nucleic acid digestion

parietal cell
gastric gland cell that secretes hydrochloric acid and intrinsic factor

parotid gland
one of a pair of major salivary glands located inferior and anterior to the ears

pectinate line
horizontal line that runs like a ring, perpendicular to the inferior margins of the anal sinuses

pepsinogen
inactive form of pepsin

peristalsis
muscular contractions and relaxations that propel food through the GI tract

permanent tooth
one of 32 adult teeth

pharynx
throat

phosphatase
brush border enzyme that digests nucleotides

**porta hepatis**
“gateway to the liver” where the hepatic artery and hepatic portal vein enter the liver

**portal triad**
bile duct, hepatic artery branch, and hepatic portal vein branch

**premolar**
(also, bicuspid) transitional tooth used for mastication, crushing, and grinding food

**propulsion**
voluntary process of swallowing and the involuntary process of peristalsis that moves food through the digestive tract

**pulp cavity**
deepest portion of a tooth, containing nerve endings and blood vessels

**pyloric antrum**
wider, more superior part of the pylorus

**pyloric canal**
narrow, more inferior part of the pylorus

**pyloric sphincter**
sphincter that controls stomach emptying

**pylorus**
lower, funnel-shaped part of the stomach that is continuous with the duodenum

**rectal valve**
one of three transverse folds in the rectum where feces is separated from flatus

**rectum**
part of the large intestine between the sigmoid colon and anal canal

**reticuloendothelial cell**
(also, Kupffer cell) phagocyte in hepatic sinusoids that filters out material from venous blood from the alimentary canal

**retroperitoneal**
located posterior to the peritoneum

**ribonuclease**
pancreatic enzyme that digests RNA

**right colic flexure**
(also, hepatic flexure) point, at the inferior surface of the liver, where the ascending colon turns abruptly to the left

**root**
portion of a tooth embedded in the alveolar processes beneath the gum line

**rugae**
fold of alimentary canal mucosa and submucosa in the empty stomach and other organs

**S saccharolytic fermentation**
an aerobic decomposition of carbohydrates

**saliva**
aqueous solution of proteins and ions secreted into the mouth by the salivary glands

**salivary amylase**
digestive enzyme in saliva that acts on starch

**salivary gland**
an exocrine gland that secretes a digestive fluid called saliva

**salivation**
secretion of saliva

**segmentation**
alternating contractions and relaxations of non-adjacent segments of the intestine that move food forward and backward, breaking it apart and mixing it with digestive juices

**serosa**
outermost layer of the alimentary canal wall present in regions within the abdominal cavity

**sigmoid colon**
end portion of the colon, which terminates at the rectum

**small intestine**
section of the alimentary canal where most digestion and absorption occurs

**soft palate**

Available for free at Connexions <http://legacy.cnx.org/content/col11761/1.1>
posterior region of the bottom portion of
the nasal cavity that consists of skeletal
muscle

**stomach**
alimentary canal organ that contributes to
chemical and mechanical digestion of
food from the esophagus before releasing
it, as chyme, to the small intestine

**sublingual gland**
one of a pair of major salivary glands
located beneath the tongue

**submandibular gland**
one of a pair of major salivary glands
located in the floor of the mouth

**submucosa**
layer of dense connective tissue in the
alimentary canal wall that binds the
overlying mucosa to the underlying
muscularis

**submucosal plexus**
(plexus of Meissner) nerve supply that
regulates activity of glands and smooth
muscle

**sucrase**
brush border enzyme that breaks down
sucrose into glucose and fructose

**tongue**
accessory digestive organ of the mouth,
the bulk of which is composed of skeletal
muscle

**transverse colon**
part of the colon between the ascending
colon and the descending colon

**upper esophageal sphincter**
skeletal muscle sphincter that regulates
food movement from the pharynx to the
esophagus

**Valsalva's maneuver**
voluntary contraction of the diaphragm
and abdominal wall muscles and closing
of the glottis, which increases
intra-abdominal pressure and facilitates
defecation

**villus**
projection of the mucosa of the small
intestine

**voluntary phase**
initial phase of deglutition, in which the
bolus moves from the mouth to the
oropharynx

**α-α-dextrin**
breakdown product of starch

**α-dextrinase**
brush border enzyme that acts on
α-dextrins
Index of Keywords and Terms

**Keywords** are listed by the section with that keyword (page numbers are in parentheses). Keywords do not necessarily appear in the text of the page. They are merely associated with that section. Ex. apples, § 1.1 (1) **Terms** are referenced by the page they appear on. Ex. apples, 1

rectum, § 5(33), 38
reflex phase, § 4(27)
regulation of salivation, § 3(13)
regulatory mechanism, § 2(7)
remin, § 4(27)
reticuloendothelial cell, § 6(43)
retroperitoneal, § 1(1)
ribonuclease, § 7(51)
right and left hepatic ducts, 47
right colic flexure, § 5(33), 37
right hepatic duct, § 6(43)
root, § 3(13), 19
ruga, § 4(27)

Available for free at Connexions <http://legacy.cnx.org/content/col11761/1.1>
rugae, 27

S saccharolytic fermentation, § 5(33)
saliva, § 3(13), 15
salivary amylase, § 3(13), 15
salivary gland, § 3(13)
salivary glands, 15
salivation, § 3(13)
secretin, 12, 49
segmentation, § 2(7), 10, 36
sensors, 12
septum, § 3(13)
serosa, § 1(1), 5
sigmoid colon, § 5(33), 37
simple columnar epithelium, 5
small intestine, § 5(33), 33
soft palate, § 3(13), 13
sphincter of Oddi, § 5(33), 33
splenic flexure, § 5(33)
stomach, 10, § 4(27), 27, 27
stratified squamous epithelium, 5
sublingual gland, § 3(13)
sublingual glands, 15, 15
submandibular gland, § 3(13)
submandibular glands, 15, 15
submucosa, § 1(1), 5
submucosal plexus, § 1(1)
sucrose, § 7(51)
sucrose, lactose, and maltose, 53

T Take notes on figure 4, 54
tenia coli, § 5(33)
teniae coli, 39
the small intestine is the workhorse of the
system, where the majority of digestion
occurs, 1
the voluntary phase, the pharyngeal phase,
and the esophageal phase, 24
They transport the protein and carbohydrate
nutrients, 6
tongue, § 3(13), 15
transverse colon, § 5(33), 37
trypsin, § 6(43), 53

U upper esophageal sphincter, § 3(13), 22
uvula, § 3(13), 14

V Valsalva’s maneuver, § 5(33), 41
vestigial, 37
villi, 35
villus, § 5(33)
vitamin absorption, § 7(51)
voluntary phase, § 3(13)

W water absorption, § 7(51)

Y You should take notes on figure 2 below, 53
You should take notes on this table., 3

α α-dextrin, § 7(51)
α-dextrinase, § 7(51)
